# 1 Basic Concurrency Primitives, Ch1

topics: interior mutability, threadsafety, runtime borrow check

# 1.1 single thread interior mutability

RefCell: borrow at runtime

Cell: value replacement, not borrow; limited to word size

## 1.2 threadsafe interior mutability

Mutex: exclusive borrow at runtime

RwLock: differentiates borrow type: exclusive vs. shared read

only

Atomics: value replacement, not borrow; limited to word size

UnsafeCell: express raw pointer to wrapped data via unsafe block; in practice wrapped by a safer interface to user

Traits for threadsafety: Send, Sync

T: Send  $\iff$  T can be transferred to another thread

T: Sync  $\iff$  T can be shared with > 1 threads; &T: Send all primitve types are Send + Sync

auto traits:

- automatically opt-in
- manually opt-out
- recursively deduced on filds of structs

un-implemented types:

```
Cell<T>: Send + Sync!
* const T / * mut T: !Send + !Sync
Rc<T>: !Send + !Sync
std::marker::PhantomdData<T> where T: !Send / !Sync
```

force opt-in for un-implemented type:

```
unsafe impl Send/Sync for T {}
```

#### 1.3 Mutex

T is usually Send(not required) in which case the Mutex gives Sync:

 $\mathrm{T:}\;\mathrm{Send}\;\Longrightarrow\;\mathtt{Mutex{<}T{>}:}\;\mathtt{Sync}$ 

logical states: unlocked, locked

owning wrapper over T

interface makes access to T safer

MutexGuard as proof of exclusive access; drop automatically triggers unlock at the end of its lifetime

efficient usage: make locked interval as short as possible

lock poisoning: when thread panics while holding the lock

- lock is released
- the invoking method call errors
- further invoking a poisoned mutex returns error and also a locked MutexGuard in case user can correct it to some consistent state

unnamed guard may not be immediately dropped in certain statements:

```
if ... /*dropped here; only boolean value needed*/ {
    ...
}
if let ... = ... {
    ... /*dropped here; may borrow from let expression*/
}
```

#### 1.4 ReaderWriterLock

```
requires T: Send + Sync:
T: Send + Sync \implies RwLock<T>: Send + Sync
```

logical staes: unl<br/>coked, locked by 1 exclusive accessor, locked by any number of shared readers

differentiating lock guards:

```
read() \implies ReLockReadGuard: Deref
write() \implies ReLockWriteGuard: DerefMut
```

writer starvation issue to cosider for fairness of access

# 1.5 Thread Signaling

## 1.6 park/unpark

park: current thread put itself to sleep

unpark: another thread wakes sleeping thread; needs handle of the sleep read from spawn() method or thread::current()

spurious wakeup due to false sharing, etc.  $\implies$  user provide a check upon wakeup

request to unpark recorded if unpark happens before park in order to avoid lost notification, but does not stack up (max of 1 unpark recorded)

## 1.7 Condition Variable

signaling events related ro protected data of mutex

methods: wait, notify

atomically unlock mutex and start waiting (to avoid lost notification)

#### 1.7.1 Communication

waiting thread:

takes MutexGuard as input unlocks mutex thread put to sleep thread wakes (via a notify of CondVar or spurious wakeup) relocks mutex and returns MutexGuard

notifying thread:

invoke notify on CondVar

#### 1.7.2 Spurious Wakeup

need additional memory to check actual event: can add this along with the original value wrapped by mutex  $\,$ 

use a loop with wait to put thread back to sleep if condition not met

usage: 1 CondVar for 1 mutex

optionally can wait with timeout parameter to unconditionally wakeup thread after timeout

## 1.8 Comparison of Interior Mutability Primitives

	value replacement	reference / borrow
1 thread	Cell	RefCell
threadsafe	Atomic	Mutex/RwLock

# 1.9 Comparison of Shared Ownership Primitives

 $\rm Rc/Arc:$  act similar to Box / smart pointer but with dropping logic to take care of deallocation for shared data

1 thread	Rc
threadsafe	Arc

# 1.10 Traits for Interior Mutability Primitives

 $T \colon \texttt{Send} \implies \texttt{Cell< T>} \colon \texttt{Send} \ + \ ! \texttt{Sync} \ (usual \ practical \ case)$ 

 $\texttt{T: !Send} \implies \texttt{Cell<T>: !Send + !Sync}$ 

 $\texttt{T: Send} \implies \texttt{RefCell<T>: Send + !Sync (usual)}$ 

T: !Send ⇒ RefCell<T>: !Send + !Sync T: Send ⇒ Mutex<T>: Send + Sync (usual)

T: !Send ⇒ Mutex<T>: !Send + !Sync

 ${\tt T: Send + Sync \implies RwLock < T > : Send + Sync (usual)}$ 

T:  $!Send / !Sync \implies RwLock<T>: !Send + !Sync$ 

# 1.11 Traits for Shared Ownership Primitives

Rc<T>: !Send + !Sync

T: Send + Sync  $\Longrightarrow$  Arc<T>: Send + Sync

## 1.12 Typical Usage Pattern

#### Arc<Mutex<T>>

where:

Arc allows threadsafe immutable sharing

Mutex allows interior mutability using references across  $\geq 1$  threads

#### Rc<RefCell<T>>

where:

Rc allows single thread immutable sharing

RefCell allows interior mutability using references in single thread

#### Rc<Cell<T>>

where:

Rc allows single thread immutable sharing

Cell allows interior mutability using value in single thread

#### Arc<Atomic<T>>

where:

Arc allows threadsafe immutable sharing

Atomic allows interior mutability using value across  $\geq 1$  threads

# 2 Atomics

fetch\_and\_modify
swap
compare\_exchange:

- ABA problem for pointer algorithms
- weak version exists for more efficient impl. on some hardware at expense of spurious wakeup

fetch\_update  $\iff$  load followed by loop with compare\_exchange\_weak and user provided computation

## 2.1 Scoped Thread

regular std::thread::spawn requires closure to be Send  $\implies$  all captures of closure are required to be Send

std::thread::scope:

borrows object of non-static lifetime that can outlive thread mustiblity rules apply

threads are automatically joined at the end of the scope

## 2.2 Lazy Initialization

execute once by 1 thread, sharable afterwards race possible from threads, but this is different from data race which causes undefined behaviour (UB)

can use CondVar / thread parking / std::sync::Once / std::sync::OnceLock to avoid wasted compute from multiple threads

#### 2.3 Move Closure

transfer ownership of value

capture variable via copying/moving instead of borrowing copying reference in a move closure in order to borrow from variable

note: Atomic does not implement Copy trait

## 2.4 Data Sharing Between Threads in General

data shared need to outlive all involved threads:

- make data owned by entire program via static lifetime (static item exists even before start of the main program
- leak an allocation and promise never to drop it from that point onward in the duration of the entire program: eg: Box::leak(Box::new(..))
  - note: 'static means the object will exist until the end of the program but may not exist at the start of the program
  - note: Copy implies when moved, the original value still exists
- reference counting: track ownership and drop when no owners

eg: std::rc::Rc: clone increments counter only and gives reference to allocation

eg:  $\mathtt{std}::\mathtt{sync}::\mathtt{Arc}:$  version of Rc that is safe between threads

use of scope and variable shadowing to reuse identifiers when cloning:

shadowing: original name is not obtainable anymore in current scope  $\,$ 

original name still obtainable in an outer scope, can clone it in another inner scope  $\,$  reference counted pointers (Rc and Arc) have same restrictions as immutable reference (&T)

mutable borrows are guaranteed at compile time  $\implies$  mutable aliasing between 2 variables does not occur; optimization to remove impossible code blocks possible

assumptions held by the compiler:

- an immutable reference exists *implies* no other mutable references to the associated data exists
- there is at maximum 1 mutable reference to an object at anytime

if such assumptions are broken, then UB exists: more wrong conclusions may be propagated through optimizations

unsafe blocks are also assumed to be sound by the compiler which means compiler may apply optimizations and elide code when feasible

## 2.5 Interior Mutability

shared reference &T: copied and sharable (not mutable) exclusive reference &  $\mathtt{mut}$  T: exclusive borrow of T

interior mutability provides more flexibility for shared data that needs mutation

Cell / Atomic: replace value, no borrow

RefCell / Mutex: runtime borrowing; book-keeping cost for existing borrows; failable at runtime

# 3 Memory Ordering

defining happens-before relations across threads

concurrent non-atomic stores to same variable causes data race  $\implies$  UB

lack of globally consistent order

thread spawn/join: automatically enforces happens-before relation

note: current theoretical model for formalizing memory ordering bug: cyclic reasoning / value out of thin air

## 3.0.1 Relaxed Ordering

- per atomic variable: a total modification order in every run of the program 

   all modifications of the said atomic variable happen in 1 order that is consistent/same from views of every thread
- multiple possible orderings may exist when the program is run multiple times, but each run satisfies a total modification order
- no happens-before relation

#### 3.0.2 Release-Acquire Ordering Pair

pairing:

store operation specified with release semantics load operation specified with acquire semantics

happens-before relation formed at runtime when load succeeds: all memory operations before release store is observable by and after acquire load

release store of an atomic variable may be modified by any number of fetch-modify / compare-exchange operations and still have a happens-before relation with an acquire load afterwards on the said atomic variable

any store of the associated atomic variable breaks the chain of a release-acquire pair (that previously starts with a release store and possibly followed with fetch-modifies/compare-exchanges)

use of non-atomic variable in different threads and borrow checker  $\implies$  may need unsafe blocks

#### 3.0.3 Release-Consume Ordering Pair

pairing:

store operation specified with release semantics load operation specified with consume semantics

happens-before relation for associated atomic variable in the release store and the dependent expressions in the consumer thread

practically, hard to define dependent evaluation and implementation tends to fallback to acquire semantics instead

# 3.0.4 Sequentially Consistent Ordering

pairing:

store operation specified with SeqCst semantics load operation specified with SeqCst semantics

guarantees of:

- acquire ordering
- release ordering

globally consistent ordering of all SeqCst operations (every SeqCst operation in a program is a part of a single total order that all threads agree on)

can replace acquire and release ordering and maintain happensbefore relation

## 3.1 Memory Fence

separate memory ordering semantics from atomic operations

it can take place of acquire / release / other memory order operations

types of fences:

- release fence
- acquire fence
- acquire-release fence
- sequentially consistent fence

# 3.1.1 Practical Replacement

without fences	with fences
release store	fence with release ordering
	atomic store (any memory ordering)
acquire lead	atomic load (any memory ordering)
	fence with acquire ordering

any atomic store following release fence is observable by any atomic load before acquire fence  $\implies$  happens-before relation is established between the release-acquire fences pairing

## 3.1.2 Practical Usages

- $\bullet\,$  can be used for multiple variables at once
- conditional fence (apply happens-before relation only after certain condition is met)

eg: place acquire fence in conditional branch that succeeds that is relevant to the atomic variable

```
let p = var.load(relaxed);
if p == ... {
  fence(acquire);
  do_something(...);
}
```

 may be more efficient if atomic variable is expected to fail in comparison often (let atomic variable be loaded with relaxed memory ordering)

## 3.1.3 SeqCst Fence

- $\bullet\,$  is both a release fence and an acquire fence
- is part of a single total order of sequentially consistent operations

#### 3.2 Compiler Fence

does not prevent processor from reordering instructions

Rust compiler fence: std::sync::atomic::compiler\_fence

uses:

- process-wide memory barriers
- special cases of signal handler/interrupt

## 3.3 FAQs

memory model is not related to timing

memory model defines order of operations and affects instruction reordering

SeqCst implies the operation depends on the total order of every single SeqCst operation in the program

⇒ usually overly tall claim

more relaxed constraints may be easier to review (eg: release-acquire pairs)

release store not form happens-before relation with SeqCst store: for a part of a globally consistent order, both operations need to be SeqCst

#### 3.4 Summary

each atomic variable has its own total modification order that all threads agree on

single thread: happens-before relations exist between every single operations  $\,$ 

unlocking a mutex happens-before locking that mutex

SeqCst results in 1 globally consistent order of operations that participates in SeqCst, but it is usually overly constraining

fences allow combining memory ordering of multiple operations for efficiency or applying conditional memory ordering for efficiency

happens-before relation exist when:

- threads spawn / join
- acquire load from a release store on an atomic variable
- fetch-modifies / compare-exchanges in between a releaseacquire pair on an atomic variable is still valid for that happens-before relation

#### 4 Processor

atomic operation compiles to machine instructions

memory ordering at lowest level of individual instructions

tool for assembly code: cargo-show-asm

instructions that cannot be represented by 1 processor instruction, use equivalent implementation with composite/multiple instructions (eg: cmpxchg and loop)

#### 4.1 x86-64

compare-exchange and compare-exchange-weak have no difference: compile to lock cmpxchg instruction

x86 lock prefix as a modifier for instructions: add, sub, and, not, or, xor, xchg(implicit), xadd, bts, btr, btc

# 4.2 RISC: load-linked/store-condition (LL/SC) Loop

used in a pair some memory address

for efficient implementation:

- false negative cna happen during store-conditional (stxr instruction): a chunk of memory tracked usually 74 bytes / 1 kB
- 1 memory address pre core can be tracked at a timeclrex (stop tracking writes to memory)  $\implies$  subsequent SC will fail

ARM64 LL/SC pair:

- ldxr
- stxr

ARMv8.1 atomic instructions:

- cas (equivalent to compare-exchange)
- fetch-\* instructions

# 4.3 Cache Coherence Protocol for Consistency Between Processor Caches

eg: EMSI, MOESI, MESIF

keep states for individual cache levels

use  $\mathtt{std}::\mathtt{hint}::\mathtt{black\_box}(...)$  to disable compiler optimization when doing performance measurement

measurable difference when writes to cache require exclusive access at the same time when other cores are tring to load on the same cache lines

add padding to separate variables in cache lines (to reduce false sharing)

eg: #[repr(align(64))] for 64 byte alignment (note: must be power of 2, cannot be mixed with packed repr)

pack variable close together if they are expected to be accessed close temporally  $\,$ 

out of order instructions/effects:

- store buffers for writing back to cache: brief moment of inconsistency present when write ops are not yet visible to other cores
- invalidation queues: invalidation requests (dropping cache line) queued for later processing
  - ⇒ inconsistency (outdated before they are dropped)
- ⇒ visibility of write ops from other cores slightly delayed

- pipelining: parallel instructions: computation on some memory finishes before preceding instructions  $\implies$  interaction with other cores (may appear out of order)
- special instructions exist to prevent these above

# 4.4 Memory Ordering

x86-64 and ARM64 are other-multi-copy atomic architectures  $\implies$  write op visible to any core  $\implies$  visible to all cores at same time

⇒ memory ordering is same as instruction reordering

x864-64 has fairly strong ordering restructions:

 $\implies$  release and acquire semantics have same cost as relaxed memory ordering

 $\implies$  (acquire  $\iff$  relaxed, release  $\iff$  relaxed)

store doesn't get reordered earlier than a preceding memory operation  $\implies$  load doesn't get reordered later than a following memory operation

 $\ensuremath{\mathsf{ARM64}}$  has relatively weak ordering: all memory ops can be reordered

acquire and release versions of loads and stores:

- $\bullet$  stlr
- $\bullet$  ldar
- ldaxr
- stlxr

none of the sepcial acquire and release instructions is reordered with any other of these special instructions  $\iff$  acquire-release operations are same as sequentially consistent operations (acquire / release / AcqRel has same cost as SeqCst)

# 4.5 Memory Fence / Barrier Instructions

prevents certain instructions being reordered past it

fences pose stronger constraint than release-acquire operations directly on atomic variables  $\implies$  release-acquire atomic ops can be logically replaced with fences but the reverse is not true

fences are not acquire or load operations

# Release Fence:

- usually used with atomic store after the release fence
- 1 way fence: memory operations before release fence cannot be reordered down past ALL subsequent memory writes after the fence (contrast with release store on atomic variable: memory operations before release op cannot be reordered down past the release op itself)

## Acquire Fence:

- usually used with atomic load before the acquire fence
- 1 way fence: memory operations after acquire fence cannot be reordered up before ALL previous memory reads before the fence
- happens-before relation is established when a release store on an atomic variable and the load of the atomic variable reads any expected value that is caused by sideeffects of the release sequence

# SeqCst Fence:

• both an release and an acquire fence

#### on X64-64:

• Acquire and Release are same as relaxed memory ordering (acquire/release fences are elided)

• SeqCst: issue of mfence instruction

## on ARM64:

• Acquire: dmb ishld

• Release: dmb ish

• AcqRel: dmb ish

• SeqCst: dmb ish (same cost as acquire and release)

## 5 OS Primitives

futex used as a basic primitive that is optimized to avoid frequent syscall

originally syscall in linux but available in supporting libraries on other OSes (can use syscall from libc crate)

use of an atomic variable for thread notifications and wakeups

fast path in userspace when non-blocking, resort to slower syscall when blocking in required

spurious thread wakeups possible, thus need a condition check solution to missing wakeup:

- use of another value:
   expected value match atomic variable ⇒ blocking wait
   otherwise ⇒ non-blocking
- wake is atomic with respect to wait:
   change atomic variable's value before wake
   thread that is about to wait will actually not block
   and skip wait therefore the wake up no longer has any
   effect
- check of expected value and wait/block (of futex\_wait) happens as a single atomic operation wrt. other futex operations

priority inversion problem:

- high priority thread blocked by another lower priority thread with lock held
- solution: allow priority inheritance temporarily when this situation occurs
- $\bullet$  see <code>FUTEX\_<OP>\_PI</code> operations

# 5.1 Implementation Variants on Other OS

Windows:

- heavy weight objects
- critical\_section
- slim reader-writer lock
- address based waiting (Wait/WakeByAddress)

MacOS:

- libc, libc++, obj-c, swift interface: pthread impl
- platform specific lightweight os\_unfair\_lock, limitations: no cond var, no reader-writer variant

## 5.2 Standards for Accessing Kernel Scheduler via Special Libs or Syscalls

POSIX for Unix based systems

pthreads extensions: provide support for threading, data types, functions for concurrency

# 5.2.1 Concerns wrt. Movable/Non-Movable Types

pthread structures are generally non-movable types due to self references

possible workarounds:

std::pin

Box<..>: issue with leaking/forgetting an object: pthread\_mutex\_destroy on locked mutex may result in undefined behaviour as per spec.

#### 5.3 Futex as an Efficient Mutex

simple futex-like addition to C++ standard:

std::atomic\_wait
std::atomic\_notify

originally added to Linux systems: SYS\_futex syscall: use of 32 bit atomic variable address to notify threads when to wake

solution for missing wakeup signal: atomic op for wait  $\implies$  a wake, between check of expect value provided to wait and the moment it goes to sleep, is not missed

manage state in userspace if possible, only rely on slower code path (via syscall) when absolutely necessary (need for a block)

usually wait used in a loop to check condition of possible spurious wakeups

futex related op arguments:

- 32 bit atomic pointer
- op constant
- optional flags, eg: FUTEX\_PRIVATE, FUTEX\_CLOCK\_REALTIME
- remaining arguments dependent on the op

futex ops:

- FUTEX\_WAIT: check and block is atomic
- $\bullet\,$  FUTEX\_WAKE: provide max of threads to wake up
- FUTEX\_WAIT\_BITSET: wake only for bits set in common from a corresponding FUTEX\_WAKE\_BITSET op
- FUTEX\_WAKE\_BITSET
- FUTEX\_REQUEUE
- FUTEX\_CMP\_REQUEUE
- FUTEX\_WAKE\_OP
- FUTEX\_PRIVATE\_FLAG

# 6 Primitive Implementation Examples

#### 6.1 Spin Lock

release store (unlock) and acquire load (lock) pair for preventation of data race (UB)  $\,$ 

std::hint::spin\_leep(): possible optimization of processor
possible implementation:

- wraps actual data inside an UnsafeCell<T> for interior mutability
- requires T: Send
- locking provides exclusive access (and provides Sync trait)
- uses unsafe blocks in function, user will not have to use unsafe
- use lock guard (representing safe access to locked data) pattern to managae lifetime of locked access to protected data;
  - implement Deref, DerefMut to access data for user ergonomics (behave similar to reference)
  - implement Drop: automatic release store (unlocking) when lifetime of the guard ends

# 6.2 Channels

#### 6.2.1 One Shot Channel

- 1 message only from 1 thread to another thread
- T: Send
- use of unsafe:
  - may be unitialized
  - non-copy data must not be duplicated
  - manual content drop may be necessary: leaking/forgetting is safe but sometimes undesirable
  - eg: std::mem::MaybeUninit<T> (unsafe version of Option<T>) for efficiency where user tracks its initialized status
  - -use  ${\tt UnsafeCell's}$  interior mutability for sharing
  - wrapping shared struct Channel requires T: Send and gives Sync in return
- use of atomic swaps for setting one time flags
- encoding of multiple states in one word and atomic compare-exchanges
- $\bullet\,$  possible use of runtime check/panic instead of letting UB happen
- use type checking from compiler to avoid errors: move/consume to avoid unwanted reuse of resources:

use of non-Copy type and pass by value / consume by called function  $\implies$  prevent caller from using that object again at compile time (elides some runtime checks)

- TX-RX pair for message passing, Channel shared inside their private implementations
- use of Arc<T> for sharing of allocation and resource dropping: RX drop and TX drop ⇒ Arc<T> drop ⇒ T drop
- Arc<T> incurs extra runtime overhead for allocation

#### • allocation optimization

- borrowing instead of memory allocation (Arc)
- use of lifetimes and mutable borrow for compile time checks
- Channel explicitly created by user ahead of time and passed in to RX and TX as references upon construction in the split method
- TX, RX take in additional lifetime parameter which
  is the same as the lifetime of the borrowed Channel:
  when TX or RX is present, existing Channel cannot
  be mutably borrowed again until TX and RX are both
  dropped
- Channel needs to outlive TX and RX for compiler check to pass
- Channel resets its contents on entry to split method in case it is used multiple times
- overwriting content for fresh initialization: after 1st borrow expires, subsequent borrows are made on these newly created resources
- blocking interface:
  - make RX object not Send, such as using a PhantomData<\* const ()> member field so that auto trait deduction for the wrapping struct is propagated to be !Send:

```
* const () : !Send \Longrightarrow PhantomData<* const ()> : !Send \Longrightarrow wrapping struct is !Send
```

- RX stays on the same thread, TX allows to cross thread boundaries
- use receiving thread's handle to invoke waking up a blocked thread (place this inside the sender struct)
- call unpark on receiving thread's handle after release store optation is performed by the sender
- recever checks Channel's variable to avoid spurious wakeup

#### 6.3 Arc

basic implementation: use a pointer type to the shared underlying data via std::ptr::NonNull, use counter info for the shared data; use NonNull::from(Box::leak(Box::new(..))) to get a pointer from initial allocation

implement ergonomic methods deref and deref\_mut

let cloning change internal counter and point to the shared data

require T: Send + Sync and give wrapping Arc<T> Send + Sync

auto traits is not active for raw pointer types (including NonNull) wrt. Send and Sync

when only find decrement needs to be acquire and all others release:

```
if var.fetchsub(1, release) == 1 {
  fence(acquire);
}
```

exclusive access to shared data, conditionally in a runtime branch, eg:

fn get-Mut(arc: & mut Self) -> Option<& mut T>
miri interpreter for simulation and verification of unsafe code
weak version of Arc<T>: Weak<T>

- T can be shared between Arc<T> and Weak<T>
- • Weak<T> does not prevent drop of T, eg: all Arc<T> dropped  $\implies$  T dropped
- Weak<T> exists without reliance of T, which can provide conditional access to & T-like object: implement upgrade function to get Option<Arc<T>> where it's None if T is already dropped

cycle breaking: use 2 counters:

- strong pointer count (data\_ref\_count)
- weak pointer + strong pointer count (alloc\_ref\_count)

wrapping struct ArcData<T>:

- use interior mutability of an optional
- keep extra info of shared counters referencing its data

drop implementation of weak pointer and strong pointer:

- strong pointer count is  $0 \implies \text{drop } T$
- weak pointer + strong pointer count dropping to 0 ⇒ droppping ArcData<T>

Rust drop order:

- run Drop::drop on object
- drop the object's fields 1 by 1 recursively

cloning pointers:

- Arc: increment weak counter, increment strong counter
- Weak: increment weak counter

dereferencing:

- Arc: unconditionally dereference since existence of Arc implies underlying T is valid
- Weak: upgrade to strong pointer
  - atomic increment and compare swap on strong counter to give out access

- upgrade and return an Arc to caller
- if strong pointer counter is  $0 \implies$  data doesn't exist and abort operation

strong pointer access to mutate data: runtime conditional chheck to allow exclusive access to  $\boldsymbol{T}$ 

- check weak pointer counter is 0, strong pointer count is
- cast underlyding data and return & mut T; safe since Arc exists

convert from strong pointer to weak pointer (downgrade): call clone on weak pointer and return the weak pointer

possible optimization: use 1 atomic counter instead of  $2 \implies$ 

- if user is not using weak pointers then they don't have to pay the cost when cloning /dropping
- use ManuallyDrop<T> instead of Option<T> to save an extra state and use existence of Arc<T> to know if data is gone or not
- let 1 weak count represets all existing Arc<T>s \iffty 1
   Arc<T> left, decrement 1 weak count associated with all of them
- downgrade and get\_mut requires more change:
- get\_mut
  - need to check 2 atomic counters
  - temporarily lock downgrade operation by use of a special value indicating locked state for weak counter; use compare-exchange on alloc\_ref\_count (weak pointer + strong pointer) variable to replace with special value if the condition applies
- downgrade
  - check that special value for alloc\_ref\_count (weak pointer + strong point counter) is not present, otherwise loop
  - compare-exchange acquire with get\_mut method on alloc\_ref\_count atomic variable: increment if success and this will make future get\_mut fail until Weak::drop makes this alloc\_ref\_count go back to 1 via release memmory ordering

#### 6.4 Locks

# 7 Additional Ideas
